

# Towards Verifying the Bitcoin-S Library

Ramon Boss, Kai Brännler, and Anna Doukmak

Bern University of Applied Sciences, CH-2501 Biel, Switzerland  
{ramon.boss,kai.bruennler,anna.doukmak}@bfh.ch

**Abstract.** We try to verify properties of the bitcoin-s library, a Scala implementation of parts of the Bitcoin protocol. We use the Stainless verifier which supports programs in subset of Scala called the *Pure Scala Fragment*. We first try to verify the property that regular transactions do not create new money. It turns out that there is too much code involved that lies outside of the supported fragment to make this feasible. However, in the process we uncover and fix a bug in bitcoin-s. We then turn to a much simpler (and less interesting) property: that adding zero satoshis to a given amount of satoshis yields the given amount of satoshis. Here as well a significant part of the relevant code lies outside of the supported fragment. However, after a series of equivalent transformations we arrive at code that we successfully verify.

**Keywords:** Bitcoin · Scala · Bitcoin-S · Stainless.

## 1 Introduction

For software handling cryptocurrency, correctness is clearly crucial. However, even in very well-tested software such as Bitcoin Core, serious bugs occur. The most recent example is the bug found in September 2018 [5] which essentially allowed to arbitrarily create new coins. Such software is thus a worthwhile target for formal verification. In this work, we set out to verify properties of the bitcoin-s library with the Stainless verifier.

**The Bitcoin-S Library.** The bitcoin-s library is an implementation of parts of the Bitcoin protocol in Scala [7,8]. In particular, it allows to serialize, deserialize, sign and validate transactions. The library uses immutable data structures and algebraic data types but is not written with formal verification in mind. According to the website, the library is used in production, handling significant amounts of cryptocurrency each day [7].

**The Stainless Verifier.** Stainless is the successor of the Leon verifier [2,9,1] and is developed at EPF Lausanne [3]. It is intended to be used by programmers without training in formal verification and thus allows to write specifications in Scala and focusses on counterexample finding in addition to proving correctness.

The following example from the Stainless documentation [6] demonstrates this. Notice how a precondition is specified using the function *require* and a postcondition using *ensuring*.

```
1 def factorial(n: Int): Int = {
2   require(n >= 0)
3   if (n == 0) {
4     1
5   } else {
6     n * factorial(n - 1)
7   }
8 } ensuring(res => res >= 0)
```

Our program happens not to satisfy the specification. An overflow in the 32-bit Int leads to a negative result for the input 17, as Stainless reports in Figure 1. Changing the type from Int to BigInt will result in a successful verification.

```

**Fig. 1.** Output of Stainless verification for calculating factorial of Int number

**The Pure Scala Fragment.** Stainless supports only a subset of Scala.

Anna It supports blabla, in particular it supports not blablabla. (check class with var)

why does stainless use its own BigInt etc?

They call this Pure Scala. You can find the specification of Pure Scala on the Stainless documentation website [6] in the section [Pure Scala](#).

In addition, Stainless has its own library with annotations, reimplementations of some core data types, collections and input-output functions and more. Some of them are described on the website in the section [Stainless Library](#). There are more details about the library in the source code of Stainless on GitHub [3] in the folder *frontends/library/stainless*.

## 2 Trying to Verify the No-Inflation Property

Thus, we try to verify the property, that a non-coinbase transaction cannot generate new coins. Let's name it the **??**.

As we can see later in chapter ??, we must rewrite a huge part of the code implementing this property. This reimplementing into Pure Scala needs a lot of time. So, we adjust the plan and verify another functionality of Bitcoin-S. Nevertheless, during the analysis of the ?? we look at a bug in Bitcoin-S found during this work and see the code changes for the bugfix in section 2.3.

This chapter describes the part of Bitcoin-S needed to verify the ?? described before. We are going to create a transaction and show the relevant parts of the method `checkTransaction`, where transactions are checked against some properties. Then, we will see the bug in Bitcoin-S found during this work and its fix. In the end we see why the ?? needed to be changed to the ??.

## 2.1 Creation of a Transaction

Some code in this section is copied or adapted from the Bitcoin-S-Core transaction builder example [?]. Bitcoin-S-Core has a bitcoin transaction builder class with the following constructor:

```

1  BitcoinTxBuilder(
2    destinations: Seq[TransactionOutput], // where to send the money
3    utxos: BitcoinTxBuilder.UTXOMap,      // unspent transaction outputs
4    feeRate: FeeUnit,                     // fee rate per byte
5    changeSPK: ScriptPubKey,              // where to send the change
6    network: BitcoinNetwork               // bitcoin network information
7  ): Future[BitcoinTxBuilder]
```

The return type `Future` does not make sense here, since the implementation calls either `Future.successful` or `Future.fromTry` which returns an already resolved `Future`. This might be for future purposes.

Now we create a transaction.

First, we need some money. Thus, we create a fake transaction with one single output. This transaction can be parsed from the bitcoin network, but we create one manually in order to see this process.

```

1  val privKey = ECPrivateKey.freshPrivateKey
2  val creditingSPK = P2PKHScriptPubKey(pubKey = privKey.publicKey)
3
4  val amount = Satoshi(Int64(10000))
5
6  val utxo = TransactionOutput(currencyUnit = amount, scriptPubKey =
7    creditingSPK)
8
9  val prevTx = BaseTransaction(
10    version = Int32.one,
11    inputs = List.empty,
12    outputs = List(utxo),
13    lockTime = UInt32.zero
14  )
```

On line one and two we create a new keypair to sign the next transaction and have a `scriptPubKey` where the bitcoins are. This is our keypair. So the money is transferred to our public key. Line four specifies the amount of satoshis we have in the transaction. Then we create the actual transaction from line 6 to 13.

Now that we have some bitcoins, we create the new transaction where we want to spend them.

First, we need some out points. They point to outputs of previous transactions. We use the index zero, because the previous transaction has only one output that becomes the first index zero. If there were two previous outputs, the second output would become the index 1 and so on.

```

1  val outPoint = TransactionOutPoint(prevTx.txId, UInt32.zero)
2
3  val utxoSpendingInfo = BitcoinUTXOSpendingInfo(
4    outPoint = outPoint,
5    output = utxo,
6    signers = List(privKey),
7    redeemScriptOpt = None,
8    scriptWitnessOpt = None,
9    hashType = HashType.sigHashAll
10 )
11
12 val utxos = List(utxoSpendingInfo)

```

This utxos are the inputs of our transaction.

Second, we need destinations to spend the bitcoins to. For the sake of convenience we create only one.

```

1  val destinationAmount = Satoshis(Int64(5000))
2
3  val destinationSPK = P2PKHScriptPubKey(pubKey = ECPrivateKey.freshPrivateKey.publicKey)
4
5  val destinations = List(
6    TransactionOutput(currencyUnit = destinationAmount, scriptPubKey = destinationSPK)
7  )

```

We spend 5000 satoshis to the newly created random public key.

Finally, we define the fee rate in satoshis per one byte transaction size as well as some bitcoin network parameters. The bitcoin network parameters are not important, so we use some static values normally used when testing.

```

1  val feeRate = SatoshisPerByte(Satoshis.one)
2
3  val networkParams = RegTest // some static values for testing

```

Now lets build the transaction with those data.

```

1  val txBuilderF: Future[BitcoinTxBuilder] = BitcoinTxBuilder(
2    destinations = destinations, // where to send the money
3    utxos = utxos,              // unspent transaction outputs
4    feeRate = feeRate,          // fee rate per byte
5    changeSPK = creditingSPK,   // where to send the change
6    network = networkParams     // bitcoin network information
7  )
8
9  val signedTxF: Future[Transaction] = txBuilderF
10 .flatMap(_.sign)                // call sign on the transaction
11   builder
12   .map {
13     (tx: Transaction) => println(tx.hex) // transaction in hex for the
14                                     bitcoin network
15   }

```

ramon: change code to get an actual transaction, completely understand and explain the code

Line one to seven creates a transaction builder which is then signed on line ten. We can now use our transaction object on line twelve. For example, after calling *hex* on it, we can send the returned string to the bitcoin network.

## 2.2 Validation of a Transaction

Bitcoin-S offers a function called *checkTransaction* located in the *ScriptInterpreter* object. This is its type signature:

```

1   checkTransaction(transaction: Transaction): Boolean

1  /**
2   * Checks the validity of a transaction in accordance to bitcoin core's
3   * CheckTransaction function
4   * https://github.com/bitcoin/bitcoin/blob/
5   * f7a21dae5dbf71d5bc00485215e84e6f2b309d0a/src/main.cpp#L939.
6   */
7  def checkTransaction(transaction: Transaction): Boolean = {
8    val inputOutputsNotZero =
9      !(transaction.inputs.isEmpty || transaction.outputs.isEmpty)
10   val txNotLargerThanBlock = transaction.bytes.size < Consensus.maxBlockSize
11   val outputsSpendValidAmountsOfMoney = !transaction.outputs.exists(o =>
12     o.value < CurrencyUnits.zero || o.value > Consensus.maxMoney)
13
14   val outputValues = transaction.outputs.map(_.value)
15   val totalSpentByOutputs: CurrencyUnit =
16     outputValues.fold(CurrencyUnits.zero)(_ + _)
17   val allOutputsValidMoneyRange = validMoneyRange(totalSpentByOutputs)
18   val prevOutputs = transaction.inputs.map(_.previousOutput)
19   val noDuplicateInputs = prevOutputs.distinct.size == prevOutputs.size
20
21   val isValidScriptSigForCoinbaseTx = transaction.isCoinbase match {
22     case true =>
23       transaction.inputs.head.scriptSignature.asmBytes.size >= 2 &&
24       transaction.inputs.head.scriptSignature.asmBytes.size <= 100
25     case false =>
26       //since this is not a coinbase tx we cannot have any empty previous
27       //outs inside of inputs
28       !transaction.inputs.exists(_.previousOutput == EmptyTransactionOutPoint)
29   }
30
31   inputOutputsNotZero && txNotLargerThanBlock &&
32     outputsSpendValidAmountsOfMoney && noDuplicateInputs &&
33     allOutputsValidMoneyRange && noDuplicateInputs &&
34     isValidScriptSigForCoinbaseTx
35 }

```

We can pass a transaction and it returns a Boolean indicating whether the transaction is valid or not. So for example when we pass the transaction we built before the returned value would be true, because it's a valid transaction. It might not be accepted by the bitcoin network but for a transaction on its own it's valid. We can not check context with it, because we can only pass one transaction.

There are several checks in *checkTransaction*. For example, it checks if there is either no input or no output. In this case we get false.

The relevant part for the bug we found:

```

1   val prevOutputTxIds = transaction.inputs.map(_.previousOutput.txId)
2   val noDuplicateInputs = prevOutputTxIds.distinct.size == prevOutputTxIds.size

```

It gathers all transaction ids referenced by the out points. When we call *distinct* on the returned list, we get a list with duplicate removed. If the size of the new list is the same as the size of the old, we know that there was no duplicate transaction id, because, as said, *distinct* removes the duplicates.

### 2.3 Fixing a Bug in Bitcoin-S

We can see that there is a bug in the `checkTransaction` function from before, recognized and fixed through this work.

Here is the relevant code of `checkTransaction` again:

```
1  val prevOutputTxIds = transaction.inputs.map(_.previousOutput.txId)
2  val noDuplicateInputs = prevOutputTxIds.distinct.size == prevOutputTxIds.size
```

What happens if we have two `TransactionOutPoints` (previousOutputs) with a different index but referencing the same Transaction ID (txId)?

According to the Bitcoin protocol this is possible. A transaction can have multiple outputs that should be referenceable by the next transaction. So this is clearly a bug.

What should not be possible is a transaction referencing the same output twice. This bug occurred in Bitcoin Core known as CVE-2018-17144 which was patched on September 18, 2018. [5]

Here, Bitcoin-S did a bit too much and marked all transaction as invalid, if they referenced the same transaction twice. The fix is, to check on `TransactionOutPoint` instead of `TransactionOutPoint.txId`, because `TransactionOutPoint` contains the txId as well as the output index it references. So in pseudo code, we check on the tuple (tx, index) instead of (tx). The fixed code:

```
1  val prevOutputs = transaction.inputs.map(_.previousOutput)
2  val noDuplicateInputs = prevOutputs.distinct.size == prevOutputs.size
```

Since `TransactionOutPoint` is a case class and Scala has a built in `==` for case classes there is no need to implement `TransactionOutPoint.==`.

This was fixed in [pull request number 435](#) on GitHub at April 23, 2019, through this work along with a unit test to prevent this bug from appearing again in the future.

### 2.4 Adjusting No-Inflation Property

*anna: what does it mean to integrate*

Trying to integrate Stainless in Bitcoin-S caused a lot of troubles, mainly because of version conflicts. For more details see chapter 4.

After integrating Stainless in Bitcoin-S, there were many errors. It takes too much time to fix them all so it should be easier to extract the classes needed for the `checkTransaction` function.

*anna: which errors?*

The extracted code has more than 1500 lines. After running Stainless on it, it still throws a huge bunch of errors about what Stainless can not reason about. After fixing some of those errors, there appear new ones. So this would require changing nearly everything of the extracted code.

Let's adjust the property from the `??` to the `??`, because there is not enough time to fix all these errors and write the verification. This is way less interesting to verify but gives still many insights in what needs to be done to verify some parts of Bitcoin-S and other source code.

So let's look at the `??`.

### 3 Towards Verifying the Addition-with-Zero Property

In Bitcoin-S there is a class `Satoshis` representing an amount of bitcoins. We look at the verification of the addition of Satoshis with zero Satoshis. This operation should result in the same amount of Satoshis. Let's call it the `??`.

Using Stainless, we see the successful verification of this property. But the process of the verification with the tool requires many changes in the code, so that Stainless can accept it. We look at all needed modifications in chapter 3.

After realizing that it would consume too much time to rewrite the Bitcoin-S code and even the extracted part with `checkTransaction`, the smallest unit in Bitcoin-S-Core that is worthwhile to verify was extracted. This could be the addition of two `CurrencyUnits`. To make it even easier, the addition of `CurrencyUnits` with zero. `CurrencyUnits` is an abstract class in Bitcoin-S, representing currencies like Satoshis.

#### 3.1 Extracting the relevant Code

kai text

extracted 2 files (they are in `code/addition/src/main/scala/addition/original`)

- changes from original to reduced (new folder): - package name
- removed numbers other than `Int64`
- removed extending `Factory`, `NetworkElement` and `BasicArithmetic`. This includes some hex/byte conversion eg `fromHex`, `hex`, `bytes`, `fromBytes`, ... Just interfaces never referenced description in section [#the-basics](#) (cannot add link with hashtag) `NetworkElement` class `Factory` class
- removed `Bitcoins` class
- removed subtraction and multiplication, binary operations `!!`, `!!`, etc, comparison operator `!|=`, `!|=`, etc but not `==` and `!=`
- removed `toBigDecimal`
- removed object `CurrencyUnits` containing some variables to transform satoshis to btc (not used)

The code we use for the following sections is in reduced folder.

ramon: write this section

ramon: keep close to original code

ramon: for every transformation: before and after

ramon,anna: for every transformation: why does it preserve the semantics

ramon,anna: add comments

ramon,anna: explain what the code does and why

Here we can see the extracted code needed for the addition of `CurrencyUnits`:

```

1 package addition.reduced.number
2
3 /**
4  * This abstract class is meant to represent a signed and unsigned number in
5  * C
6  * This is useful for dealing with codebases/protocols that rely on C's
7  * unsigned integer types
8  */

```

```

8 sealed abstract class Number[T <: Number[T]] {

74   lazy val one = Int64(1)
75

```

```

76 lazy val min = Int64(-9223372036854775808L)
77 lazy val max = Int64(9223372036854775807L)
78
79 def apply(long: Long): Int64 = Int64(BigInt(long))
80
81 def apply(bigInt: BigInt): Int64 = Int64Impl(bigInt)
82 }

1 package addition.reduced.currency
2
3 import addition.reduced.number.{BaseNumbers, Int64}
4
5 sealed abstract class CurrencyUnit {
6   type A
7
8   def satoshis: Satoshis
9
10  def !=(c: CurrencyUnit): Boolean = !(this == c)
11
12  def ==(c: CurrencyUnit): Boolean = satoshis == c.satoshis
13
14  def +(c: CurrencyUnit): CurrencyUnit = {
15    Satoshis(satoshis.underlying + c.satoshis.underlying)
16  }
17
18  protected def underlying: A
19 }
20
21 sealed abstract class Satoshis extends CurrencyUnit {
22   override type A = Int64
23
24   override def satoshis: Satoshis = this
25
26   def toBigInt: BigInt = BigInt(toLong)
27
28   def toLong: Long = underlying.toLong
29
30   def ==(satoshis: Satoshis): Boolean = underlying == satoshis.underlying
31 }
32
33 object Satoshis extends BaseNumbers[Satoshis] {
34
35   val min = Satoshis(Int64.min)
36   val max = Satoshis(Int64.max)
37   val zero = Satoshis(Int64.zero)
38   val one = Satoshis(Int64.one)
39
40   def apply(int64: Int64): Satoshis = SatoshisImpl(int64)
41
42   private case class SatoshisImpl(underlying: Int64) extends Satoshis
43 }

```

The additions' signature looks like this:

```
1 +(c: CurrencyUnit): CurrencyUnit
```

When we run Stainless on this code (without any properties to prove), it throws the following errors:

```

[ Error ] Code.scala:41:1: Objects cannot extend classes or implement traits,
         use a case object instead
         object Int64 extends BaseNumbers[Int64] {
         ~~~~~~
[ Error ] Code.scala:60:3: Stainless doesn't support abstract type members
         type A

```

```

~~~~~
[ Error ] Code.scala:77:33: Only literal arguments are allowed for BigInt.
      def toBigInt: BigInt = BigInt(toLong)
      ~~~~~
[ Error ] Code.scala:84:1: Objects cannot extend classes or implement traits,
      use a case object instead
      object Satoshi extends BaseNumbers[Satoshi] {
      ~~~~~
[ Info ] Shutting down executor service.

```

So let's see how we can fix those errors.

### 3.2 Turning Object into Case Object

Stainless output:

```

[ Error ] Code.scala:41:1: Objects cannot extend classes or implement traits,
      use a case object instead
      object Int64 extends BaseNumbers[Int64] {
      ~~~~~
[ Error ] Code.scala:84:1: Objects cannot extend classes or implement traits,
      use a case object instead
      object Satoshi extends BaseNumbers[Satoshi] {
      ~~~~~

```

Here, we can just change the objects from object to case object. Stainless recommendation is to use objects for modules and case objects as algebraic data types.

This is due to the internal design of Scala. It's possible to reason about case object but not about object. This needs a fundamental knowledge of Scala and some functional paradigms that should not be part of this thesis. The [issue number 520](#) on Stainless GitHub gives some thoughts, if you want to know more.

### 3.3 Getting Rid of Abstract Type Member

Stainless output:

```

[ Error ] Code.scala:60:3: Stainless doesn't support abstract type members
      type A
      ~~~~~

```

This should be easy to rewrite by using generics instead of an abstract type, right? Unfortunately not. The problem is, CurrencyUnit uses one of its implementing classes: Satoshi.

Simplified code.

```

1 sealed abstract class CurrencyUnit {
2   type A
3
4   def +(c: CurrencyUnit): CurrencyUnit =
5     Satoshi(satoshi.underlying + c.satoshi.underlying)
6

```

```

7     protected def underlying: A
8   }
9
10  sealed abstract class Satoshi extends CurrencyUnit {
11    override type A = Int64
12  }

```

What happens, if we typify `CurrencyUnit` with `A`, meaning to make it generic with type `A`?

`Satoshi` extends `CurrencyUnit` with type `Int64`, so it would be of type `CurrencyUnit[Int64]`. That's too specific, because the return type of the addition is then `CurrencyUnit[Int64]` not `CurrencyUnit[A]`. Maybe the Bitcoin-S developers should reimplement this part and not use `Satoshi` directly.

Since there is no easy way to fix it and the code should stay as much as possible the original, we just remove the abstract type and set it to `Int64`. This limits the verification a bit, but as we only want to verify the addition in `satoshi`, that's OK.

### 3.4 Replacing the `BigInt` Constructor Argument With A String Literal

Stainless output:

```

[ Error ] Code.scala:77:33: Only literal arguments are allowed for BigInt.
          def toBigInt: BigInt = BigInt(toLong)
                                ~~~~~

```

As described before, Stainless supports only a subset of Scala. The `BigInt` from the Stainless library is a bit restricted. One such restriction is, that `BigInt` does not support dynamic `BigInt` construction. Thus, the constructor parameter of `BigInt` must be a literal argument.

Again, a simplified code version.

```

1  sealed abstract class Satoshi extends CurrencyUnit {
2    def toBigInt: BigInt = BigInt(toLong)
3    def toLong: Long = underlying.toLong
4  }

```

This would be really hard to refactor, because Bitcoin-S tries to be as dynamic as possible so it can be used with cryptocurrencies other than bitcoins. Maybe it could be impossible, because they need to parse dynamic values from the bitcoin network.

Luckily, we can use `toBigInt` on the field `underlying` directly instead of `toLong`. So, instead of converting the `underlying` to `Long` and back to `BigInt` we convert `underlying` directly to `BigInt`.

After fixing all Stainless errors, a new error appears.

### 3.5 Getting Rid of Special Generics

Stainless output:

```

[ Error ] Code.scala:7:30: Unknown type parameter type T
    sealed abstract class Number[T <: Number[T]]
                                ~~~~~

```

This is a missing feature in Stainless. It does not support upper type boundaries on the class itself. To track this, [issue 519](#) was created on GitHub during this work.

```
1 sealed abstract class Number[T <: Number[T]] extends BasicArithmetic[T]
```

Despite this, in order to be able to continue, we make this a concrete type by replacing T with Int64. Int64, because Satoshi's uses only Int64. There are other number types like UInt16 but for our property we don't need them.

Now, there are two new errors.

### 3.6 Getting Rid of Concrete Type

Stainless output:

```
[Warning ] Code.scala:9:3: Could not extract tree in class: type A =
      BigInt (class scala.reflect.internal.Trees$TypeDef)
      type A = BigInt
      ~~~~~
```

This is easy. We just replace all occurrence of A with BigInt, since A is not overwritten in an implementing class. This is not the exact same code, because an implementing class can not override A anymore but that's fine for our verification.

This was a missing feature in Stainless that was fixed on May 28, 2019 with [pull request 470](#) on GitHub. Now it should work without this change.

### 3.7 Replacing the BigInt &-Function With Bound Check

Stainless output:

```
[ Error ] Code.scala:22:14: Unknown call to & on result (BigInt) with arguments
      List(Number.this.andMask) of type List(BigInt)
      require((result & andMask) == result,
      ~~~~~
```

Due to the restrictions on BigInt, we can not use the & function either. Simplified code:

```
1 sealed abstract class Number extends BasicArithmetic[Int64] {
2   def andMask: BigInt
3
4   override def +(num: Int64): Int64 = apply(checkResult(underlying + num.
      underlying))
5
6   private def checkResult(result: BigInt): BigInt = {
7     require((result & andMask) == result, "Result was out of bounds, got: ")
8     + result
9   }
10 }
```

This is a bounds check. It checks if the result of the addition is in range of the specified type, which is now the hard coded `Int64`.

So, we can replace the `&` mask with a bound check whether the result is in range of `Long.MinValue` and `Long.MaxValue`, because `Int64` has the same 64-bit range as `Long`. Again the code gets a bit more static and it's not the exact same code anymore.

Running `Stainless` produces again new errors.

### 3.8 Extracting Private Inner Classes

Stainless output:

```
[Warning ] Code.scala:90:3: Could not extract tree in class: case private
      class SatoshiImpl extends Satoshi with Product with Serializable {
```

Stainless can not extract the private class inside the object. Bitcoin-S uses this a lot, because they separate the class from its implementation. Simplified:

```
1  object Int64 extends BaseNumbers[Int64] {
2    private case class Int64Impl(underlying: BigInt) extends Int64
3  }
```

This is easy to fix. We just extract the private class out of the object. This is not exactly the same code, because other classes in the same file could now access the private class. But for our property it does not change anything.

Now we get some weird warnings about `require`.

### 3.9 Removing Second Parameter of `Require`

Stainless output:

```
[Warning ] Code.scala:51:3: Could not extract tree in class: scala.this.Predef
      .require(Int64Impl.this.underlying.>=(math.this.BigInt.long2bigInt(
      -9223372036854775808L)), "Number was too small for a int64, got: "
      .+(Int64Impl.this.underlying)) (class scala.reflect.internal.Trees$Apply)
      require(underlying >= -9223372036854775808L,
      .....
[Warning ] Code.scala:53:3: Could not extract tree in class: scala.this.Predef
      .require(Int64Impl.this.underlying.<=(math.this.BigInt.long2bigInt(
      9223372036854775807L)), "Number was too big for a int64, got: "
      .+(Int64Impl.this.underlying)) (class scala.reflect.internal.Trees$Apply)
      require(underlying <= 9223372036854775807L,
      .....
[ Error  ] checkResult$0 depends on missing dependencies: require$1.
```

Seems like `Stainless` does not support the second string parameter of `require` or at least it throws a warning about it. We can safely remove the string parameters from the `requires`, since they only serve as error messages.

A new error appears.

### 3.10 Rewriting BigInt Comparison with Long

Stainless output:

```
[ Error ] inv$4 depends on missing dependencies: long2bigInt$0.
```

This error is hard to understand, but we can see that there is a missing Long to BigInt conversion. So we search for all Long values in the code.

```
1 private case class Int64Impl(underlying: BigInt) extends Int64 {
2   require(underlying >= -9223372036854775808L)
3   require(underlying <= 9223372036854775807L)
4 }
```

Looks like it can not compare a BigInt with a Long value. We can easily convert this Long value to a BigInt with a string literal parameter by passing these numbers as strings to the BigInt constructor.

Finally, we get some output from Stainless about the verification in the code.

```
[...]
[Warning ] => INVALID
[Warning ] Found counter-example:
[Warning ]   thiss: { x: Object | @unchecked isNumber(x) } -> Int64Impl(0)
[Warning ]   num: { x: Object | @unchecked isInt64(x) }   -> Int64Impl(9223372036854775808)
[...]
[ Info ] + precondition. (call checkResult(thiss, underlying(thiss) + u ...) invalid Code.scala:16:45
[...]
[ Info ] total: 5 valid: 4 (4 from cache) invalid: 1 unknown: 0 time: 1.317
```

This shows that there is an invalid specification in checkResult and Stainless prints a counterexample for it.

Let's ignore this for a moment and write the specification for the ??.

### 3.11 Writing Specification for the Property

As specified, our verification must only support addition with zero. So we restrict the parameter to be zero in the precondition.

```
1 require(c.satoshis == Satoshi.zero)
```

We ensure the result is the same value as *this* in the postcondition.

```
1 ensuring(res => res.satoshis == this.satoshis)
```

We can use equals (==) directly on Satoshi, because it is a case class. The addition will now look like this:

```
1 override def +(c: CurrencyUnit): CurrencyUnit = {
2   require(c.satoshis == Satoshi.zero)
3   Satoshi(satoshis.underlying + c.satoshis.underlying)
4 } ensuring(res => res.satoshis == this.satoshis)
```

That's all we need to verify our addition.

Now we will look into the previous error.

### 3.12 Propagating Require

There is another problem with Bitcoin-S. Bitcoin-S-Core uses `require` as a fail-fast method whereas Stainless needs it to verify the code.

The Stainless output again:

```
[Warning ] Found counter-example:
[Warning ]   thiss: { x: Object | @unchecked isNumber(x) } -> Int64Impl(0)
[Warning ]   num: { x: Object | @unchecked isInt64(x) }    -> Int64Impl(9223372036854775808)
```

Corresponding code:

```
1 sealed abstract class Number extends BasicArithmetic[Int64] {
2   override def +(num: Int64): Int64 = apply(checkResult(underlying + num.
3     underlying))
4
5   private def checkResult(result: BigInt): BigInt = {
6     require(
7       result <= BigInt("9223372036854775807")
8       && result >= BigInt("-9223372036854775808")
9     )
10    result
11  }
```

But how does Stainless find a counter example ignoring the `require` in `checkResult`? Since Stainless is a static verification tool, it tests every possibility. So it can use a number bigger than the maximum `Int64` and pass it to the addition. The `require` in `checkResult` fails.

Thus, we need to add the restriction from `checkResult` to the addition too.

```
1 override def +(num: Int64): Int64 = {
2   require(
3     num.underlying <= BigInt("9223372036854775807")
4     && num.underlying >= BigInt("-9223372036854775808")
5     && this.underlying <= BigInt("9223372036854775807")
6     && this.underlying >= BigInt("-9223372036854775808")
7   )
8   apply(checkResult(underlying + num.underlying))
9 }
```

Stainless finds another counter example:

```
[Warning ] Found counter-example:
[Warning ]   num: { x: Object | @unchecked isInt64(x) }    -> Int64Impl(1)
[Warning ]   thiss: { x: Object | @unchecked isNumber(x) } ->
Int64Impl(9223372036854775807)
```

Sure, when adding one to the maximum `Int64` the `require` does not hold anymore. Since we do only allow zero as a parameter, the easiest way is to restrict it to zero here too.

### 3.13 Result

Finally, everything is green and correctly verified.

The verified code.

```

```

But is it really the original code that we verified? And why did we have to change that much? This and other questions will be answered in the next chapter.

## 4 Practical Challenges with Stainless

In this chapter we look at the practical challenges that could occur by using Stainless. Since Stainless is still in development and there is no 1.x release there might still be breaking changes and improvements fixing problems described now.

### 4.1 sbt vs JAR

We can either use the sbt plugin or a JAR file to check code with Stainless.

Invoking the JAR on our source code Stainless will verify it. If we have a bigger project, this becomes really tricky, because we must pass all files needed including the dependencies. This is in contrast to the sbt plugin, where we can integrate Stainless in our compilation process. When we call compile, Stainless verifies the code and stops the compilation if the verification fails.

Having a static version configured in the sbt build file, every developer has the same Stainless features available. This should prevent incompatibility with new or deprecated features when we use different plugins.

So the sbt plugin has clear advantages over the JAR file since its integrated directly. We do not have to download it manually and find the right version and if we bump the version we can just edit it in the build file and every developer is on the same version again.

However, currently there are some drawbacks. For example the sbt plugin does not always report errors. We will see more about that shortly.

## 4.2 Integration into Bitcoin-S

During this work, Stainless updated the sbt plugin to support sbt 1.2.8 from 0.13.17 and Scala 2.12.8 from 2.11.12. So this section might be out of date now.

Stainless requires and Scala recommends Java SE Development Kit 8. Newer Java versions won't work.

To use the latest version of the sbt tool you have to build it locally. You can run `sbt universal:stage` in the cloned Stainless git repository. This generates `frontends/scalac/target/universal/stage/bin/stainless-scalac`.

Bitcoin-S-Core uses sbt 1.2.8 and Scala 2.12.8, while Stainless sbt plugin is on sbt 0.13.17 and Scala 2.11.12.

Sbt introduced new features in the 1.x release used by Bitcoin-S. Most of them can be written the sbt 0.13.17 way.

The bigger problem is, due to the different Scala and sbt versions, the following error after trying to go in a sbt shell:

```
[warn] There may be incompatibilities among your library dependencies; run 'evicted'
      to see detailed eviction warnings.
[error] java.lang.NoClassDefFoundError: sbt/SourcePosition
...
Project loading failed: (r)etry, (q)uit, (l)ast, or (i)gnore?
```

Downgrading Bitcoin-S sbt version to 0.13.17 fixes the error but then it can not load some libraries only compiled for newer versions. So this would take too much time to fix and changes the Bitcoin-S code inadvertently.

The next approach is to use the stainless cli instead of sbt. Running stainless on all source files does not work, because dependencies are missing. The parameter `-classpath` can resolve it but the value of this parameter must be the paths to all the dependencies separated by a `'.'`. Finally, `core` depends on `secp256k1jni`, another package of Bitcoin-S written in Java. So this needs to be in the source files to.

The final command looks like this in `core` folder of Bitcoin-S:

```
$ stainless
  -classpath " :$(find ~/.ivy2/ -type f -name *.jar | tr '\n' ':') "
  $(find . -type f -name *.scala | tr '\n' ' ')
  $(find ../secp256k1jni -type f -name *.java | tr '\n' ' ')
```

*.ivy2* is the dependency cache of sbt. The *tr* replaces the first char with the second so a newline with either ':' or ' '.

With this command, Stainless throws the next error:

```
[Internal] Error: object scala.reflect.macros.internal.macroImpl in compiler mirror
not found.. Trace:
[Internal] - scala.reflect.internal.MissingRequirementError$.signal
(MissingRequirementError.scala:17)
...
[Internal] object scala.reflect.macros.internal.macroImpl in compiler mirror not found.
[Internal] Please inform the authors of Inox about this message
```

So we can not know how many errors will face us. Let's go another way, because the errors may take too much time and it might lead to a next error. We extract the code needed to verify a transaction mainly the class `Transaction` and `ScriptInterpreter` with many other classes they're depending on.

After this extraction Stainless was successfully integrated with both sbt and JAR.

Running `sbt compile` in the project with Stainless ended without error. But it also ended with no output. So we are not able to change the code so Stainless would accept it since we do not know what to change.

So the sbt plugin does not always complain where the JAR file did. The open [issue 484 on GitHub](#) might describe exactly this error.

Now we can finally run Stainless on our code. But this leads us to the next findings. We must rewrite most of the code, as described in the previous chapters.

## 5 Conclusion

Because of the limitations of the verification tool, we could only verify a rewritten version of the original Bitcoin-S code. So we can not guarantee the correctness of the addition of Satoshis with zero in Bitcoin-S. Not all changes we made were as trivial as the replacement of objects with case objects. For these non-trivial changes, as seen for example the bound check in section 3.7, we cannot say whether they are equivalent to the original implementation or not.

So code should be written specically with formal verification in mind, in order to successfully verify it. Otherwise, it needs a lot of changes in the software because verification is mathematical and the current software is written mostly in object-oriented style. Software written in the functional paradigm would be much easier to reason about.

Thus, either Stainless must find ways to translate more of built-in object-oriented patterns of Scala to their verification tool or developers must invest more in functional programming.

Also, we found that trying to verify code reveals bugs as shown in section 2.3. Finally, our work led to some feedback to the Stainless developers to improve the tool.
